Abstract

Central and Eastern Europe (CEE) have experienced considerable instability in mortality since the 1960s. Long periods of stagnating life expectancy were followed by rapid increases in life expectancy and, in some cases, even more rapid declines, before more recent periods of improvement. These trends have been well documented but to date, no study has comprehensively explored trends in lifespan variation. We improve such analyses by incorporating life disparity as a health indicator alongside life expectancy, examining trends since the 1960s for 12 countries from the region. Generally life disparity was high and strongly fluctuating over the period. For nearly 30 of these years, life expectancy and life disparity moved independently from one another, largely because mortality trends ran in opposite directions over different ages. Furthermore, we quantified the impact of large classes of diseases on life disparity trends since 1994 using a newly harmonized cause of death time series for 8 countries in the region. Mortality patterns in CEE countries were heterogeneous and run counter to the common patterns observed in most developed countries. They contribute to the life expectancy-disparity discussion by showing that expansion/compression levels do not necessarily mean lower/higher life expectancy or mortality deterioration/improvements.

Introduction

The 20th century was marked by sizable improvements in mortality and health in most countries in the world ([World Health Organization 2000](#)). However, these improvements were unevenly shared in the second half of the past century, as parts of Central and Eastern Europe experienced an unprecedented period of stagnation and, in some countries, decrease in life expectancy at birth around the mid-1960s ([Human Mortality Database 2016](#)). The long term combination of a failure to complete the epidemiologic transition by reducing cardiovascular diseases ([Caselli et al. 2002](#)), along with fluctuation in alcohol and violence, particularly in the countries of the former Soviet Union (FSU) ([Bye 2008](#), [Leon et al. 1997](#)), led to lower levels of life expectancy and larger within-country mortality inequalities according to education level in this region compared to western countries in Europe ([Mackenbach et al. 2008](#)). The high mortality among young men is at the heart of the unstable Eastern European trends in life expectancy ([McKee and Shkolnikov 2001](#)). For example, male life expectancy stagnated at a level between 65 and 70 years from the 1960s to the mid-1980s in most countries of the region. Russia experienced the lowest male life expectancy in the region over this period, which was followed by a brief period of sizable improvements in life expectancy due to Gorbachev’s anti-alcohol campaign ([Leon and Shkolnikov 1998](#)). After 1987 the mortality experiences in the region diverged. Life expectancy increased continuously in parts of Central Europe. The rest of the countries, particularly those from the former Soviet Union, experienced a pronounced period of deterioration up to the mid-1990s. Mortality increases among Russian and Latvian men were especially sharp, with life expectancy losses of around 7.5 years between 1987 and 1994, which led to levels not seen since the 1950s ([Shkolnikov et al. 2001](#)). Since the mid-1990s, life expectancy has mostly been increasing throughout the region, but at different rates. As a result, large regional differences in survival have emerged. For instance, the 2010 gap in male life expectancy between Slovenia and Russia was more than 13 years ([Human Mortality Database 2016](#)).

National trends in life expectancy are important and have been extensively studied in the region ([Meslé 2004](#), [Meslé et al. 2000](#), [Rychtarikova 2004](#), [Shkolnikov et al. 2001; 2006](#), [Leon 2011](#)). Nonetheless, as an average, life expectancy conceals considerable heterogeneity in individual mortality trajectories ([Edwards and Tuljapurkar 2005](#), [Wilmoth and Horiuchi 1999](#)). This age-at-death variation, hereafter referred to as life disparity or lifespan variation, is an important dimension of inequality as it summarizes this heterogeneity at the population level and uncertainty in the timing of death at the individual level. Until now, trends in lifespan variation have mostly been studied in the context of mortality decline at all ages ([Edwards and Tuljapurkar 2005](#), [Smits and Monden 2009](#), [Vaupel et al. 2011](#)). Alongside increases in life expectancy, ages at death have become more predictable (i.e. lifespan variation has decreased). This is because mortality decline over young ages has outpaced mortality decline at older ages, compressing most deaths into a narrower age window ([Vaupel et al. 2011](#)).

This need not be the case. At the subpopulation level, numerous instances have been documented of lifes-

pan variation increase occurring alongside increases in life expectancy ([van Raalte et al. 2014](#), [Sasson 2016](#), [Seaman et al. 2016](#), [Brønnum-Hansen 2017](#)), mainly due to stalls in working age mortality decline occurring alongside continued old age mortality decline. To date, no comprehensive studies of lifespan variation have been undertaken under periods of life expectancy decline.

We complement the existing literature by focusing on the Central and Eastern European case, which shows atypical periods of mortality upheaval and substantial life expectancy changes. This region is particularly interesting because its age pattern of mortality change was very different from that observed in western countries ([Meslé 2004](#)). Since the largest deviations in age-specific mortality occurred over working ages ([Rehm et al. 2007](#)), it is a priori unclear what the net effect would be on variability. We analyzed how lifespan variation has changed since the 1960s for 12 countries from this region and determined the ages and causes of death that contributed the most to the observed change in lifespan variation, with a particular focus on the impact of alcohol-attributable mortality.

Data & Methods

Dispersion measure & demographic methods

For each population, we investigated life expectancy and lifespan variation since birth. We decided not to analyze variability at death conditioned on survival to a childhood age, as previous studies have done (e.g. [Edwards and Tuljapurkar \(2005\)](#), [Smits and Monden \(2009\)](#)), because of the arbitrariness of choosing a starting age and because infancy and childhood are major contributors to lifespan inequalities that we did not want to overlook. We focused on five periods determined by trends in the coefficient of variation of male life expectancy. The periods were labeled “Stagnation” from 1960 to 1980, “Improvements” from 1980 to 1988, “Deterioration” from 1988-1994, “Divergence” between 1994 and 2000, and “Convergence” thereafter. Periods were initially determined using a divisive hierarchical estimation algorithm for multiple change points analysis.¹ The statistical break points were 1960, 1976, 1986, 1993 and 2001. We instead used complete decades or historical events which made the interpretation of the results easier, which were all within 3 years of the cut points. For example, the period 1960-1979 (complete years) included the two decades with no substantial changes in the coefficient of variation between life expectancies. The next break point (1986) was extended to 1988 to include completely Gorbachev’s anti-alcohol campaign, which was implemented in the period 1985-1988. The following break point was used exactly since it allows the period 1988-1993 to include the dissolution of the Soviet Union in late 1991 and the largest drops in life expectancy in Russia, Latvia, Estonia, Lithuania, and less marked in Ukraine, Belarus, and Bulgaria in 1992-1993. Finally, the year 2001 was changed to 2000 to start with the 21st century.

Several dispersion measures have been proposed to analyze lifespan variability ([van Raalte and Caswell](#)

¹Using the package `ecp` in *R*

2013, Wilmoth and Horiuchi 1999). In this article, we use life disparity (e^\dagger) as a dispersion indicator (Vaupel and Canudas-Romo 2003). It is defined as the average remaining life expectancy when death occurs; or life years lost due to death. For example, when death is highly variable, some people will die well before their expected age at death, contributing many lost years to life disparity. When survival is highly concentrated around older ages, the difference between the age at death and the expected remaining years decreases, and life disparity gets smaller. It can be expressed as

$$e^\dagger = \int_0^\omega d(a)e(a)da \quad (1)$$

where $d(a)$, ω and $e(a)$ are the deaths distribution, the open-aged interval (110+ in our case), and remaining life expectancy, respectively.² We selected this measure because of its easy public health interpretation, which equals the average life expectancy losses attributable to death (Shkolnikov et al. 2011), and its decomposable and additive properties (Zhang and Vaupel 2009). The e^\dagger measure has the additive property that, once it has been decomposed by age between two periods, the sum of every age-specific contribution to the difference is the total change in e^\dagger between these two periods. These properties allow us to quantify the impact of mortality at different ages, and from different causes, and to separate ages that decrease lifespan variability from those that increase it by using demographic methods (Zhang and Vaupel 2009, Shkolnikov et al. 2011). An important attribute of e^\dagger is the so-called threshold age at which mortality improvements have zero effect on lifespan variation (Zhang and Vaupel 2009). Progress in saving lives below this age reduces variation (also called premature deaths), whereas progress above this age increases variation in lifespans (Vaupel et al. 2011).

The decomposition method used in this paper is based on the line integral model (Horiuchi et al. 2008). Suppose f (e.g. e^\dagger) is a differentiable function of n covariates (e.g. each age-cause specific mortality rate) denoted by the vector $\mathbf{A} = [x_1, x_2, \dots, x_n]^T$. Assume that f and \mathbf{A} depend on the underlying dimension t , which is time in this case, and that we have observations available in two time points, t_1 and t_2 . Assuming that \mathbf{A} is a differentiable function of t between t_1 and t_2 , the difference in f between t_1 and t_2 can be expressed as follows:

$$f_2 - f_1 = \sum_{i=1}^n \int_{x_i(t_1)}^{x_i(t_2)} \frac{\partial f}{\partial x_i} dx_i = \sum_{i=1}^n c_i, \quad (2)$$

where c_i is the total change in f (e.g. e^\dagger) produced by changes in the i -th covariate, x_i . The c_i 's in equation (2) were computed by numerical integration following the algorithm suggested by Horiuchi et al. (2008). This method has the advantage of assuming that covariates change gradually along the time dimension.

We decomposed changes in life expectancy and lifespan variation by single age, period and cause of death. For the age-cause decomposition we used the 5-year age group mortality rates from the Human Cause-of-Death Database (2016). All the calculations were performed using *R* (R Core Team 2000) and are fully

²The discrete formula from lifetable functions used is $\sum_{x=0}^{109} [d(x)(e(x) + a(x) * [e(x+1) - e(x)]) + d(110+) * e(110+)]$

reproducible with the available [code](#) and additional information.

The close relationship with other lifespan variation indices, such as Keyfitz’s life table entropy ([Vaupel and Canudas-Romo 2003](#)), and the high correlation between them suggests that conclusions would likely be the same regardless of the measure chosen ([van Raalte and Caswell 2013](#), [Vaupel et al. 2011](#), [Wilmoth and Horiuchi 1999](#)).

Data

We used all-cause death counts, population exposures and period life tables from the [Human Mortality Database \(2016\)](#) for 12 countries from 1960 to the most recent year available in the data set. The countries included in the study were from what will subsequently be referred to as *Central Europe* (Bulgaria, Czech Republic, Hungary, Poland, Slovakia, Slovenia), *the Baltic countries* (Estonia, Latvia, and Lithuania), and other former Soviet countries (*FSU*) (Belarus, Russia, Ukraine). Data for Slovenia was only available from 1983. The data are by single age, year, sex and country.

Cause of death data came from the newly developed [Human Cause-of-Death Database \(2016\)](#), which provides coherent cause-specific mortality data time series from 1994 to 2010 for eight of the countries in the study (Belarus, Czech Republic, Poland, Russia, Ukraine, Estonia, Latvia and Lithuania). For inclusion into the database, a universal and standardized methodology was undertaken to redistribute deaths between 104 disease categories in 5-year age groups. We used these data to get the cause-specific proportion by 5-year age groups. This has effectively eliminated ruptures surrounding revisions of the International Classifications of Disease (ICD), and substantially reduced cross-country comparability problems owing to different coding practices, particularly from the use of ill-defined and unknown causes. We truncated the cause-of-death analysis at age 85 because of classification quality and presence of comorbidities and focus on the period after 1994 because comparable information is available for the eight countries ([Human Cause-of-Death Database 2016](#)). Furthermore, we focus on this period because it coincides with the beginning of the divergence in Eastern European mortality trends, particularly between the former Soviet and Central European countries ([Meslé 2004](#)).

Cause of death classification

We grouped causes of death into the following broad categories, with a harmonized time series from 1994 to 2010: deaths wholly attributable to alcohol, circulatory disease, transport accidents, other external causes, infectious and respiratory diseases, cancers, and rest of causes (for details on the ICD-10 codes for each cause, see [Table 1](#)).

Our objective in classifying disease was twofold. First we aimed to see which broad causes of death were the important drivers in changing life disparity levels over the period. Second, knowing that injurious alcohol consumption has long been identified as a major determinant of premature mortality in Eastern European countries, particularly of the FSU (Leon et al. 1997, McKee et al. 2005, McKee and Shkolnikov 2001, Rehm et al. 2007, Zaridze et al. 2009; 2014, Grigoriev and Andreev 2015), we aimed for a classification that could at least partially shed light on mortality change due to changing alcohol patterns and mortality change owing to improvements in lifestyle and medical care.

Attributing mortality to alcohol is not straightforward. For one, unlike smoking, heavy alcohol consumption can have both immediate and cumulative impacts on mortality. In any period certain causes, for instance traffic accidents or alcohol poisoning, may change immediately in response to changing consumption patterns, while others, for instance liver cirrhosis, mainly reflect past consumption behaviour (Menon et al. 2001, Rehm et al. 2003), and still others are such as ischemic heart disease (part of circulatory disease) have been implicated in both immediate binge drinking mortality (Kauhanen et al. 1997) and elevated mortality risks from long-term heavy drinking (Roerecke and Rehm 2014). Thus using a cause of death based attribution method is only sensible in countries with relatively stable temporal patterns of alcohol consumption (Kraus et al. 2015, Martikainen et al. 2014), which is certainly not the case in our study.

Instead we grouped causes by the degree to which they associate with alcohol consumption and abuse and further large categories that have undergone major changes through the epidemiologic transition. Deaths wholly attributable to alcohol refer to those health conditions that by the ICD definition identifies alcohol consumption as a necessary cause and that previous research has identified as wholly attributable to alcohol consumption (Rehm et al. 2010). We additionally include liver cirrhosis in this first category because around three-quarters of deaths from this cause in the region are thought to be attributable to alcohol (Rehm et al. 2003), and it is common practice to include it as a condition attributable to alcohol consumption (Rehm et al. 2003; 2010). However, circulatory disease and transport accidents are also amenable to alcohol consumption, meaning that while many of these deaths do not relate to alcohol, changes in hazardous alcohol consumption would be expected to increase or decrease the baseline levels. As such we pay careful attention to when these two causes co-move with large changes in causes wholly attributable to alcohol. Although additional rare causes of death can be linked to alcohol consumption, we do not include them in our study because their absolute contributions to mortality change are likely to be very small in the set of countries that we study (Grigoriev and Andreev 2015).

[Table 1 about here]

In what follows, we present our results on Central and Eastern European males only. Mortality change

was larger and more abrupt among men, which more clearly illustrates the added value of looking to lifespan variation in times of crisis. In most cases, trends were similar for both sexes, but the magnitude of change was less for females. Full results are presented in the supplemental material for females.

Results

Age specific rates of mortality improvement

For a descriptive look at age-specific mortality change over the period, we first examined the average annual rate of mortality improvement (Rau et al. 2013) with smoothed mortality surfaces (Camarda 2012) for males in the 12 Central and Eastern European countries 1. The respective values are expressed in percent. Little change or no improvement (-0.5% to 0.5%) is depicted in white. Improvement in mortality (i.e. mortality decline) is shown in blue and mortality increase in red. Darker tones mean major changes in mortality rates.

Almost every country experienced a near-continuous period of increasing mortality rates, from the mid-1960s to the mid-1980s. Mortality rate increases were mainly concentrated in the ages between 20 and 80 years. After 1985, mortality decreased for a period of around 5 years, most sharply in the BC and FSU. Opposing this trend, in the early 1990s the same countries that had made the most progress in reducing mortality experienced intense mortality increases, particularly over working ages. Finally, since the mid to late 1990s trends in the region diverged: CE countries experienced mortality reduction over nearly every age, as did the BC of Latvia and Estonia. Russia, Ukraine and Lithuania experienced a second sharp period of mortality increase over working ages in the early 2000s, while age-specific trends in Belarus fell somewhere in between the BC and other FSU countries. Since the mid-2000s, all countries have experienced mortality improvement.

[Figure 1 about here]

Trends in life expectancy and lifespan disparity

Figure 2 shows male e_0 and e^\dagger trends for Central and Eastern European countries from 1960 to the most recent year available. From 1960 to 1984 e_0 stagnated for most of the countries, some of them even experienced a slow and steady decline (e.g. Russia, Latvia, Estonia, and Ukraine). This period was followed by a notable increase in e_0 in the mid-1980s, closely corresponding to, although sometimes preceding, Gorbachev's anti-alcohol campaign shaded in red. However, after 1987 life expectancy among these countries started to diverge: CE countries experienced a short period of stagnation or decline followed by an upward trend until the end of the study. The BC and other FSU countries experienced a marked decrease in e_0 from 1988

to 1994. From that point on, e_0 improved everywhere, with the exception of Lithuania and the other FSU countries. These last countries exhibited a final decrease (Russia, Lithuania) or stagnation (Belarus, Ukraine) in e_0 between 1998 and the mid-2000s, followed by sharp increases in the final period from the mid-2000s to the latest available year. Estonia experienced particularly rapid improvements in e_0 since the mid 1990's, especially among women (appendix Fig 2).

Life disparity showed similar patterns of stagnation between 1960 and 1980 as was seen for e_0 . Russia and Lithuania exhibited the highest levels in this period, between 17 and 19 years lost due to death; while the Czech Republic presented the lowest level throughout the same years, between 13 and 14 years. Importantly, the Czech Republic was not the regional record e_0 holder during these years. Around the mid-1980s all countries experienced compression of mortality, i.e. decreases in e^\dagger , with the exception of Hungary. After 1991, Russia and the Baltic countries experienced significant increases in e^\dagger with the peak in 1994-1995. During this peak, the observed e_0 levels differed from historic levels observed when e^\dagger was equally high. CE experienced continuous reductions in e^\dagger after 1994, whereas it was less systematic in Latvia and Lithuania. The rest of the countries also experienced declines after that year up to 2010-2014, but with greater fluctuation. Such declines, however, were not as steep as the e_0 increases in these countries.

[Figure 2 about here]

Absolute and relative changes in life expectancy and lifespan disparity

Contrasting the changing levels of e_0 and e^\dagger from Figure 2 suggests that in periods of stagnation and mortality upheavals similar levels of e_0 do not correspond to similar levels in e^\dagger . Therefore, we analyzed the direction and magnitude of change in the two measures.

Figure 3 depicts absolute and relative yearly changes (first differences) in e_0 and e^\dagger for males by period. The periods are grouped by the changes in life expectancy trends depicted in Figure 2: stagnation³ from 1960 to 1980, improvements from 1980 to 1987, deterioration from 1987-1994, divergence from 1994-2000, and convergence over the period 2000-2010. If a negative relationship existed between e_0 and e^\dagger , changes would concentrate in the top left and bottom right quadrants. If points fell in the top right and bottom left quadrants, the relationship was positive. We focus on the latter changes and quantify their frequency in three different time periods relating to overall mortality trends. Grey dots correspond to a negative association between life expectancy and life disparity (e.g. increases in e_0 with decreases in e^\dagger), while red dots correspond to a positive association (e.g. increases in e_0 with increases in e^\dagger). Since Russia is both the largest country included in the analysis and the country with the most volatile mortality trends, we marked

³We labelled the period as “stagnation”, even though some countries experienced a steady decline, because the coefficient of variation of life expectancies during this period was stagnant.

its points in dark blue. Absolute changes (top panel) are easy to interpret since they reflect the changes in life expectancy and life disparity measured in years. However, since the maximum value of e_0 is much higher than the maximum value of e^\dagger , it is not surprising that changes vary more strongly on the e_0 axis than the e^\dagger axis. Therefore, it is also important to analyze changes in both measures in relative terms (bottom panel). This allows us to quantify the intensity of such changes.

During 1960-1980, almost one-third of the yearly changes in mortality resulted in e_0 decreases and decreases in e^\dagger , in both males (35.5%, 95% CI [29.1,41.8]) and females (32.7 [26.5,38.9]). These were mostly small changes corresponding to less than one year of life. Conversely, 20.0% [14.7,25.3] (males) and 24.6% [18.9,30.2](females) of e_0 increases corresponded to e^\dagger increase. This means that, by adding both quadrants, the measures in this period were moving in the same direction more than half of the time. A similar patterns was observed in the period 1980-1988. In 1988-1994, when most of the changes corresponded to substantial decreases in e_0 , the two indices moved in the same direction about a fifth of the time. Finally in the period 1994 onwards, characterized by mortality convergence, around a third of all points related to movements in the same direction for both measures.

Moreover, even when the two measures moved in the direction expected from a negative correlation, the magnitude of change in life expectancy did not reflect the same magnitude of change in life disparity. For example, Russia lost 3 years of male life expectancy (around 5%) between 1992 and 1993, while life disparity showed a much smaller increase (less than 2.5%). Most of the time, however, e^\dagger experienced larger relative changes than e_0 , evidenced by more movement along the horizontal than the vertical axis in the bottom panel of Figure 3.

[Figure 3 about here]

Age-specific decomposition

In Figures 4-6, countries are ordered alphabetically within each region (CE, BC and FSU) and differentiated by the background color: light grey for Central Europe, light red for Baltic countries, and light blue for other former Soviet countries. Figure 4 shows age-specific contributions to the change in e^\dagger for ages 5 and above⁴, respectively, by period (results for ages 0-4 depicted in Supplemental material Figure 7⁵). The periods are the same as in the previous Figure: stagnation (blue), improvements (green), deterioration (red), divergence (purple), and convergence (orange). The threshold age occurred around the age groups where changes in lifespan variation were usually the lowest by period (e.g. Russia ages 55-59, Slovakia 65-69,

⁴For age-specific contributions to life expectancy, see the supplemental material.

⁵Declines in mortality below age 5 were the strongest age-category contributor to changes in life disparity over the period under study, with most of the decline occurring over the 1960-1980 period. For this reason they are plotted separately from other ages with a different scale used on the x -axis in the supplemental material. The decline was near monotonic in most countries, with only minor differences between countries, especially when compared to the much larger between-country differences at other ages.

Slovenia 70-74). Bars on the left (decreases in variation) came about from mortality decrease at young ages or increase at old ages, separated by the threshold age. Conversely, bars on the right (increase in variation) were produced by mortality increase at young ages or mortality decrease at old ages. If the colors were all lined up on one side it suggests that mortality changed in different directions for younger compared to older ages.

Over the long period of e_0 stagnation (blue), changes in e^\dagger were driven by mortality increase at all ages above around age 20, which expanded age at death variability in young-adult ages; and compressed variation at older ages in all countries. It is worth noting that these changes mostly offset each other since the old age compression was comparable to the net expansion of mortality experienced by children and younger adults. In fact, in Bulgaria and Belarus, the compression caused by mortality increase over older ages was greater than the expansion made by mortality increase among younger ages.⁶ A similar pattern was observed during the period of e_0 deterioration among Baltic and other FSU countries following the collapse of the FSU (red). Lifespan variability mostly increased, which was explained by expansion of mortality at young and middle ages, alongside smaller compression at older ages during this period. By contrast Central European countries experienced little change in mortality during this period.

Opposing these trends, over the period of improvements during the 1980s (green), the BC and other FSU followed a western pattern with e^\dagger decreases mostly caused by mortality decline at younger ages outpacing mortality decline over older ages and leading to overall compression in mortality. Mortality change was smaller and the age patterns of change were more variable in CE during this period. From 1994 onward (purple and orange), all countries experienced e^\dagger compression at younger ages and expansion at older ages overall. However in the early years (1994-2000), mortality increases at younger ages led to increases in e^\dagger in FSU before reversing itself in recent years. Importantly, during this post-1994 period, mortality changes at relatively young ages (20-50) had the largest impact on e^\dagger changes

[Figure 4 about here]

The contribution of different causes of death to changes in lifespan variability

Table 2 shows the net contribution of different broad causes of death to changes in life disparity for the most recent periods of divergence (1994-2000) and convergence (2000-2010). From 1994 to 2010 all the countries included in our study experienced decreasing e^\dagger . Life disparity was reduced by nearly a year in CE, equally spread out between both periods, and owing primarily to mortality from transport accidents and cancers. In BC, e^\dagger declined by between 1.2 (Latvia) and 2.8 (Estonia) years. Declines were strong over both periods, driven by transport accidents, other external causes, and mortality wholly attributable to alcohol

⁶Increasing mortality at older ages might have been an artifact due to improvements in data quality (see Limitations section).

(Lithuania, 1994-200). Finally, the other FSU countries showed little change in e^\dagger over the earlier period, and strong declines in the second period. Like with the other country groupings, changes in other external mortality seemed to be driving net changes in e^\dagger . Belarus was the only country to experience increases in e^\dagger from causes of death that were wholly attributable to alcohol.

[Table 2 about here]

Figure 5 breaks these cause of death contributions down by age for 1994-2000.⁷ The sum of the age-specific contributions by causes of death result in the values in Table 2. In CE countries, mortality decline was driven predominately by circulatory disease, but because these declines were spread before and after the threshold age, the net impact on e^\dagger was small. Causes that were completely attributable to alcohol showed no change over the period, and reductions in external mortality were comparatively minor, which suggests that circulatory disease mortality reductions were not related to changing alcohol consumption in the region. In BC circulatory disease mortality reduction was strong overall, but particularly over older ages, explaining why its net contribution over all ages was to increase e^\dagger . Declines in external cause mortality including traffic accidents below age 50 were the largest contributors to e^\dagger decline. Alcohol-attributable mortality over these ages also declined, especially in Lithuania. Taken together, this suggests that reductions in hazardous alcohol consumption played some role in reducing e^\dagger over the period in BC. Finally, in the other FSU countries, mortality declines over all ages were weaker, while trends in major causes of death were inconsistent over age.

From 2000-2010 all countries experienced improvements in survival and decreases in e^\dagger , although from a different mixture of causes (Figure 6). In CE reductions in early adult cancers and circulatory disease predominated, with reductions in external mortality including traffic accidents being of secondary importance. The BC were heterogeneous over this period—Estonia experienced sharp reductions in circulatory disease mortality at all ages, and external cause mortality below age 50. Lithuania experienced virtually no change in circulatory disease mortality, some decrease in external cause mortality below age 30 and increases in mortality attributable to alcohol over ages 30-44. Latvia fell somewhere in between the two countries. Life disparity also declined in the other FSU countries mainly because of declines in external cause mortality. However the e^\dagger declines were noticeably less in Ukraine, while circulatory diseases there actually increased at older ages, unlike in Russia and Ukraine which experienced sharp and moderate declines in circulatory disease mortality at these older ages.

[Figures 5 & 6 about here]

⁷For age-cause-specific contributions to life expectancy in the same periods, see the supplemental material.

Limitations

The limitations of our study should be mentioned. First, different measures of inequality differ from one other in formal properties and in the degree of their sensitivity to age-specific mortality change ([van Raalte and Caswell 2013](#)). Other authors have chosen measures of relative inequality, such as the Gini coefficient, Keyfitz’s entropy or the Theil index of inequality ([Shkolnikov et al. 2003](#), [Moser et al. 2005](#), [Smits and Monden 2009](#), [Colchero et al. 2016](#)). As a robustness check, we performed a sensitivity analysis replicating all the results shown in this study with the Gini coefficient following [Shkolnikov et al. \(2003\)](#) (see supplemental material). We did not find major differences with the results discussed in this article.

We chose not to decisively partition mortality into alcohol and non-alcohol related mortality because of the difficulties in determining the proportion of deaths from circulatory disease and external causes that are related to alcohol. Instead we took a more cautious approach that aimed to at least partially attribute the changes in mortality trends to alcohol consumption without over or under-interpreting its absolute impact on mortality, based on the co-movements of these causes with known causes of death that are wholly attributable to alcohol. An alternative would have been to derive alcohol-attributable mortality from follow-up longitudinal studies that report consumption patterns. Even if such surveys were available for some countries included in the study, self-reported alcohol consumption data are often biased and underestimate actual consumption because individuals forget drinking occasions, underrate drink size and are not able to remember the quantity of drinks in every drinking session ([Livingston and Callinan 2015](#), [Bellis et al. 2009](#)). A third commonly used approach is to link mortality with changes in alcohol sales ([Evgeny 2010](#)). A limitation to this approach is that the total alcohol consumption might not matter so much as the alcohol consumption behaviour. Indeed low levels of alcohol consumed at a regular basis may even be protective against mortality ([Bell et al. 2017](#), [Rehm et al. 2010](#), [Klatsky et al. 1974](#), [Roerecke and Rehm 2014](#)). Moreover, alcohol sales do not include homemade alcohol, which is substantial in the region ([Popova et al. 2007](#), [McKee et al. 2005](#)), and can be distorted by alcohol tourism ([Mäkelä and Österberg 2009](#), [Rabinovich et al. 2009](#)).

There could be concerns with the quality of the data used in a comparative temporal setting. First, the FSU and Central European countries used a less strict definition of live births compared to the WHO definition, which had the result of artificially depressing infant mortality levels ([Aleshina and Redmond 2005](#), [Unicef and others 2003](#)). All countries eventually shifted to the WHO definition, although the timing of this shift differed between and within countries, with some regions beginning the shift even before the dissolution of the FSU ([Anderson and Silver 1986](#), [Aleshina and Redmond 2005](#), [Unicef and others 2003](#)). Since indices of lifespan variation are comparatively more sensitive to changes in infant mortality than life expectancy ([van Raalte and Caswell 2013](#)), we investigated whether our results would be robust to the following assumptions: (1) a doubling of infant mortality prior to 1990, followed by a linear decrease to 10 percent higher rates in

2000, and constant inflation of 10 percent thereafter,⁸ and (2) mortality conditional upon survival to age 5. While these scenarios created some differences in the direction of trends, particularly over the communist period where infant mortality decline was substantial, our two main conclusions from this period still held: (1) life expectancy and life disparity moved independently during the years before the fall of the Berlin wall, (2) trends in life disparity were especially driven by trends in early adult mortality. The results of these robustness checks are available in the online Appendix.

Second, the [Human Mortality Database \(2016\)](#) data used in this project is the highest quality and most comparable data available for the region. However, the data quality differs between countries, age groups and periods, and is well documented in the database. The main data quality concerns which have been flagged in the region include: age heaping and likely age exaggeration in many FSU countries and Bulgaria in the 1960s ([Grigoriev 2017](#), [Jasilionis 2017b](#), [Jdanov and Shkolnikov 2017](#), [Pyrozhevskiy et al. 2017](#), [Philipov and Jasilionis 2017](#)); lower quality data above age 80 in Belarus in the 1970s ([Grigoriev 2017](#)) and Russia after the mid-1990s ([Jdanov and Shkolnikov 2017](#)); and consistency problems in population estimates in Lithuania for the 1960s and 1970s ([Jasilionis and Stankuniene 2017](#)), in Estonia during the 1990s ([Jasilionis 2017a](#)) and in Slovenia ([Jasilionis 2017c](#)). Age heaping is less of a problem for life table summary measures, but age exaggeration is difficult to correct for and could have led to artificially worsening mortality at older ages as data quality improved. While a degree of caution should be applied in interpreting mortality differences and trends for these periods, age groups and countries, even if we were to exclude all instances of these flagged problems, the broader patterns of mortality development that we document here still hold.

Third, in the Soviet era ill-defined cardiovascular diseases were often classified as 'atherosclerotic cardiosclerosis', which is a subset of ischemic heart diseases ([Jasilionis et al. 2011](#), [Shkolnikov et al. 2012](#)). Different countries abandoned this practice at different rates, which had the effect of misclassifying deaths between the IHD, stroke and 'other circulatory disease' categories. While some degree of misclassification within circulatory disease is corrected for by the [Human Cause-of-Death Database \(2016\)](#) team ([Pechholdová et al. 2017](#)), for comparative purposes we felt it safer to combine all circulatory disease categories.

Finally, there could be concern about data quality relating to high emigration throughout the post-Soviet period. However, robustness checks conducted for Poland and Czech Republic ([Fihel and Pechholdová 2017](#)) and the Baltic countries ([Jasilionis et al. 2011](#)) showed that underestimated emigration resulted in an over-estimation of life expectancy of up to four months in Poland during the intense outflows following accession to European Union, but in other countries and periods was usually equivalent to less than one month.

⁸[Kingkade and Sawyer \(2001\)](#) published adjustment factors which were generally much lower than the doubling that we used here. Thus this adjustment should be seen as a conservative rather than realistic adjustment to test the robustness of our findings. For the 1960-1980 period, inflating the infant mortality by anywhere up to 77% for males and 95% for females resulted in yearly changes in life expectancy and life disparity moving in unexpected directions up to 50% (see https://demographs.shinyapps.io/CEE_App/)

Discussion

We analyzed and compared a long time series of life disparity for 12 countries from Central and Eastern Europe. Decomposing these trends by age and cause of death shed light into the determinants of lifespan variation across time and countries. Over the study period, the acute mortality crises of the 1990s caused greater year-to-year fluctuation in lifespan variation than in life expectancy. Life expectancy and life disparity moved independently from one another, particularly during periods of life expectancy stagnation caused by uneven age-specific mortality change. Changes in life disparity were, to a large extent, caused by changes in mid-life mortality, with different net effects depending on the country and time period.

Changes in life expectancy (e_0) and life disparity (e^\dagger)

Previous studies have found a close negative correlation between life expectancy and life disparity when measured over all ages (Wilmoth and Horiuchi 1999, Vaupel et al. 2011, Colchero et al. 2016). These studies were carried out over long periods of a hundred years or more, and mostly included Western countries with near-monotonic life expectancy increases. Importantly, two major phenomena were observed from the mid-nineteenth Century to the present: first was a drastic reduction of infectious disease mortality followed later by a major decline in cardiovascular disease mortality. These epidemiological changes can equally be considered as a redistribution of deaths from young to middle ages and later from middle to older adult ages (Robine 2001). In both cases, contemporaneous mortality decline over “younger” ages (defined as ages that compress mortality into a smaller age interval) outpaced decline over “older” ages (ages where mortality decline leads to deaths occurring over a larger age interval), which caused life disparity to decrease in lockstep with life expectancy increase.

Central and Eastern European countries ran counter to this narrative. Although they too experienced the sharp declines in infectious disease mortality up to the mid-twentieth Century, mortality at mid-life stalled or even increased for most of the last half of the twentieth Century (McKee and Shkolnikov 2001), with no appreciable declines in cardiovascular mortality until very recently (Caselli et al. 2002, Grigoriev et al. 2014, Meslé 2004, Timonin et al. 2017). As our results made clear, mortality change at different ages was far from even, with the result that changes in lifespan variation did not correspond in intensity or in the desirable direction with changes in life expectancy. i.e. an increase in life expectancy with a decrease in lifespan variation. For example, it was apparent that between-country differences in lifespan variation have and continue to be larger (in relative terms) than between-country differences in life expectancy (coefficients of variation for e_0 and e^\dagger in 2014 are 0.06 and 0.11, respectively).

From a public health perspective, these results are important because they disclose inequalities underlying population health that could not be identified by looking at life expectancy alone. As previously noted, the full distribution of deaths is characterized not only by the mean (life expectancy), but also by the dispersion in ages at death (Edwards and Tuljapurkar 2005). Periods of increasing lifespan variability underscore both a rise in within-group heterogeneity at the population level and increasing uncertainty about the timing of death at the individual level. Similar episodes have been found previously for some countries and they are seen as outliers that are not following the classic western trend (Wilmoth and Horiuchi 1999). For instance, stagnating or increasing lifespan variation has been seen alongside life expectancy increase among lower socioeconomic groups or regions in Europe, driven by mortality stagnation among young adults (van Raalte et al. 2014, Brønnum-Hansen 2017, Seaman et al. 2016). In the United States, lower educated groups have experienced both life expectancy decreases and increases in lifespan variation (Sasson 2016). More recently, much attention has been paid to poor trends in mid-life mortality among white Americans, particularly females (Case and Deaton 2015, Montez and Zajacova 2013). As noted by Gillespie et al. (2014), the challenge of reducing young-adult mortality could anticipate a new pattern characterized by increases in lifespan inequality. Our results are further proof of the independence of the two measures during long periods with atypical mortality schedules and illustrate the need to monitor lifespan variation for a complete picture of population health.

At the same time, our results revealed a paradox of sorts. On the one hand, between-country differences in lifespan variation were more stable than between-country differences in life expectancy. On the other hand, changes in lifespan variation were more sensitive to year-to-year mortality fluctuations than life expectancy, particularly when viewed on a relative scale. Measures of dispersion are more sensitive to mortality change in early mid-life than life expectancy (van Raalte and Caswell 2013). Mortality between ages 25 and 50 experienced larger changes in response to crises than older adult mortality over the period, seen clearly in Figure 1. This explains why life disparity showed greater year-to-year fluctuation than life expectancy. Meanwhile, mortality differences over older working ages and among the early retired have a larger impact on life expectancy than life disparity. This is because these ages are found on either side of the threshold age, with mortality declines (or increases) often offsetting each other, so that the net impact is no change in lifespan variation. As a result, the combination of mortality changes over younger ages with growing mortality differentials at older adult ages can lead to widening between-country inequalities in life expectancy, alongside stable life disparity differences.

Cause-of-death contributions to changes in e^\dagger after 1994

The impact of alcohol on mortality has been extensively studied in Russia, which experienced the largest mortality swings in the region (Leon et al. 1997, Rehm et al. 2007, Shkolnikov et al. 2013; 2001). Alcohol-

related mortality is also known to have played an important role in mortality trends since the 1980s in the Baltic and other countries of the FSU ([Rehm et al. 2007](#), [Jasilionis et al. 2011](#)), although its specific impact on lifespan variation has not been thoroughly investigated. To date, only [Shkolnikov et al. \(2003\)](#)’s study on Russia between 1979 and 1989 has analyzed the ages and causes of death contributing to changing lifespan variation in the region. They found that mortality compression due to reduction of death rates at early-adult ages during this period was attributed to a decrease in alcohol-related mortality as a consequence of Gorbachev’s anti-alcohol campaign. We extended this cause-of-death analysis to include more countries (Belarus, Czech Republic, Estonia, Latvia, Lithuania, Poland, Russia and Ukraine), and focused on the 1994-2010 post-Soviet years.

Fluctuating alcohol-related mortality was an important component of the moving life disparity trends in the countries of the former Soviet Union, although it occurred to different degrees in each region, and manifested itself in different causes. Over young ages, a large role was found for the reduction of external cause mortality including traffic accidents in the Baltic countries throughout the period, and in Russia, Belarus and Ukraine from 2000 onwards. Since these causes often co-moved with mortality directly attributable to alcohol over these ages it is suggestive that healthier patterns of alcohol consumption were contributing to these reductions in life disparity. At older ages, between-country differences in mortality reduction seemed to be driven by the extent of mortality reduction from circulatory diseases. Alcohol consumption was not the only factor that explained mortality trajectories in the region, or the sole explanation for difference between life expectancy and lifespan variation levels with western European countries. Other factors, such as environmental pollution, medical care, smoking behaviors and diet have been important determinants of health outcomes in this region since at least 1970 ([Bobak and Marmot 1996](#)). Indeed, the strong declines in circulatory disease mortality in the Baltic countries ([Jasilionis et al. 2011](#)), and more recently Russia ([Grigoriev et al. 2014](#)) have been seen as hopeful signs that these countries are finally on a path toward the lower levels of cardiovascular mortality that have been achieved in the west.

In contrast to the Baltic and other FSU countries, the smoother trends in life disparity found in Central Europe were driven by sustained declines in circulatory disease and cancers, with external causes playing a much smaller role, and no change in mortality directly attributable to alcohol. This is consistent with others who have argued that the steady post-1990 improvements in mortality in the region were attributable to a combination of improvements in medicine, a reorganization of the health care system, and general shifts toward healthier behavior including improving diets and reductions in smoking ([Pajak and Kozela 2011](#), [Zatonski et al. 1998](#), [Fihel and Pechholdová 2017](#), [Cífková et al. 2010](#), [Cooper et al. 1984](#), [Rychtarikova 2004](#), [Nolte et al. 2000a;b](#)). We additionally identified a recent stagnation (since 2010) in Russian lifespan variation. By looking into decomposition results after 2010, our results suggest that this could be a result of a slowdown in mortality improvements below age 60 offset by larger progress above this age. A recent article

by [Timonin et al. \(2017\)](#) suggests that this could be a result of uneven progress in reducing cardiovascular mortality at the subregional level in Russia offset by convergence in under-60 mortality.

Preventing external mortality at young ages has been previously highlighted as an immediate factor to reduce lifespan variability, and differences in life disparity between populations. [Firebaugh et al. \(2014\)](#) argued that allocating resources to reducing homicides in the American black population was more likely to narrow racial disparities in lifespan variation than tackling more common causes of death. In this sense, most reductions in life disparity in the region were caused by improvements in mortality at young ages after 1994, particularly in external causes. The decline in these causes of death also increased life expectancy ([Trias-Llimós et al. 2017](#)), and contributed toward convergence between countries in the region in lifespan variation, as we showed. Similarly to some developed countries such as Canada, France, Germany, Japan, among others ([Seligman et al. 2016](#)), reduction in mortality from cancers and cardiovascular diseases helped to increase life expectancy in CEE, but they did not account for most life disparity reductions.

Mortality associated to the most hazardous forms of alcohol consumption, such as alcohol liver disease or poisoning by exposure to alcohol, did not play a central role in lifespan variation levels or trends. In part, this might be because these are small causes of death to begin with in comparison to much larger causes of death such as circulatory disease or external cause mortality. Nevertheless, some countries, namely Lithuania, Russia and Latvia did show large mortality improvements in these conditions which caused compression of mortality at young ages. These differences have been pointed out previously as a partial explanation for different mortality trends in Lithuania and Belarus ([Grigoriev et al. 2015](#)).

Lifespan variation, in this case e^\dagger , is a measure of aggregate health inequality that reveals fundamental differences in levels and trends across the countries that we studied. Therefore, analyzing lifespan dispersion together with life expectancy contributes to a deeper understanding of the impact of changing mortality trends on population health. Our results show not only that Central and Eastern European countries experienced high lifespan variation and consequently greater fluctuation in the predictability of lifespan, but also that life expectancy and life disparity were able to move independently, particularly in periods of stagnation in life expectancy. These uncommon findings, opposing those observed in most developed countries, show that expansion (compression) levels do not necessarily mean lower (higher) life expectancy or mortality deterioration (improvements) when the yearly changes over time are taken into account.

Figures and tables

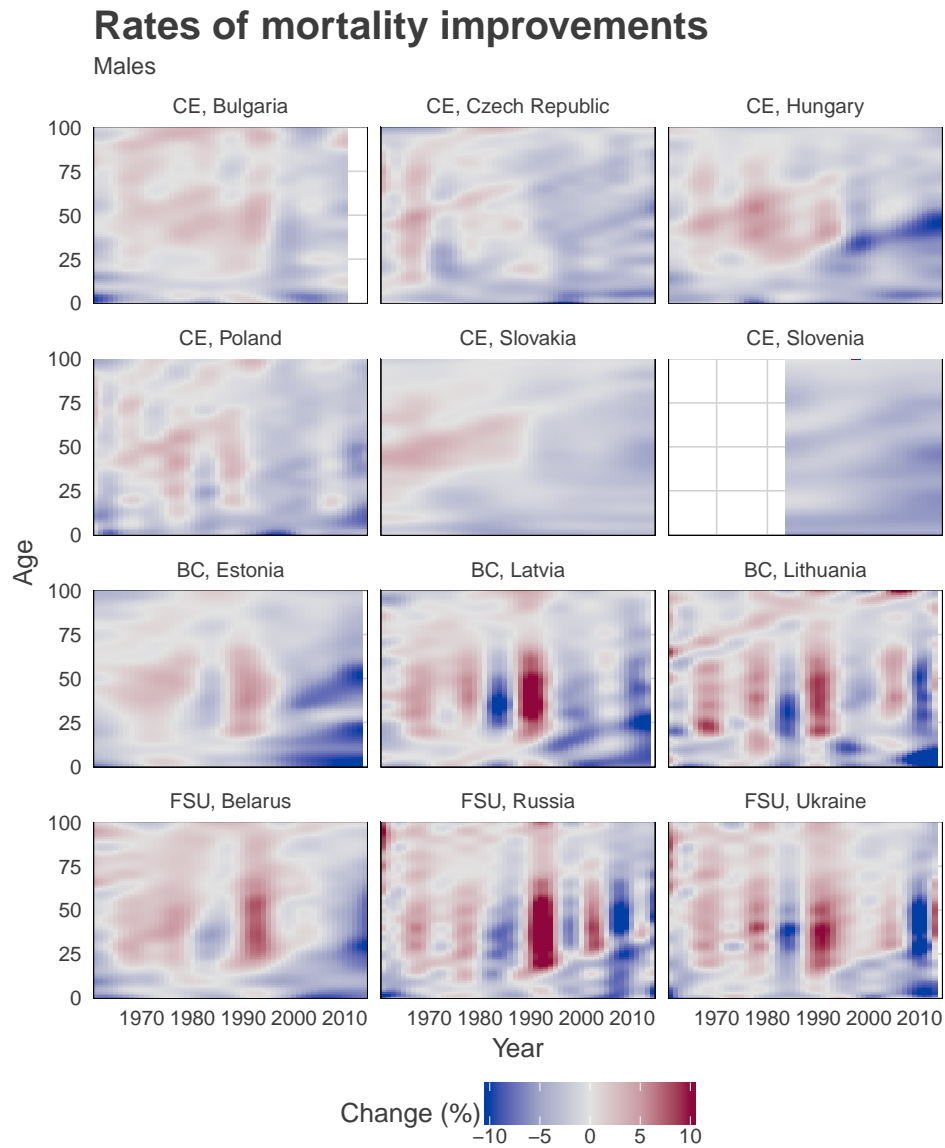

Table 1: Classification of causes-of death amenable to alcohol consumption

Category	ICD-10 codes
1) Alcohol attributable conditions	
Mental and behavioral disorders due to use of alcohol, alcohol liver disease and cirrhosis of the liver, poisoning by exposure to alcohol	F10, K70 & K74, X45
2) Amenable to alcohol consumption	
Cardiovascular diseases (Ischemic Heart Diseases, stroke, rheumatic heart diseases; essential hypertension; hypertensive disease; pulmonary heart diseases; non rheumatic valve disorders; cardiac arrest; heart failure; other heart diseases; sequelae of cerebrovascular disease; diseases of arteries, arterioles and capillaries, other circulatory diseases) and transport accidents	I20-25, I60-I67 & G45, I00-I09; I10; I11-I15; I26-I28; I34-I38; I46; I50; I30-I33, I40-I45, I47-I49; I51; I69; I70-I78; I80-I99, and V01-V99
3) Other conditions amenable to alcohol consumption	
Other external causes (Accidental exposure to smoke, fire and flames; accidental poisoning by other substance; suicide and self-inflicted injuries; assault; event of undetermined intent; complication of medical and surgical care, accidental falls, accidental drowning and submersion, other accidental threats to breathing, other accidents and late effects of accidents)	(X00-X09; ; X40-X44, X46-X49; X60-X84; X85-Y09, Y35, Y36; Y10-Y34; Y40-Y84, W00-W19, W65-W74, W75-W84, W20-W64, W85-W99, X10-X39, X50-X59, Y85-Y91, Y95-Y98)
4) Residual causes	
Rest of conditions and mortality above age 85	

Table 2: Cause-specific contributions to the change in e^\dagger for males, 1994-2000 & 2000-2010

Period	Group	Country	Attributable to alcohol	Circulatory	Other external	Transport accidents	Infect. & resp.	Cancers	Rest	Total
